#### Abstract

Hundreds of papers and hundreds of factors attempt to explain the cross-section of expected returns. Given this extensive data mining, it does not make any economic or statistical sense to use the usual significance criteria for a newly discovered factor, e.g., a t-ratio greater than 2.0. However, what hurdle should be used for current research? Our paper introduces a multiple testing framework and provides a time series of historical significance cutoffs from the first empirical tests in 1967 to today. We also project forward 20 years assuming the rate of factor production remains similar to the experience of the last few years. We argue that today a newly discovered factor needs to clear a much higher hurdle, with a t-ratio greater than 3.0. Echoing a recent disturbing conclusion in the medical literature, we argue that most claimed research findings are likely false.

## 1 Introduction

Forty years ago, one of the first tests of the Capital Asset Pricing Model (CAPM) found that the market beta was a significant explanator of the cross-section of expected returns. The reported t-ratio of 2.57 in Fama and MacBeth (1973) comfortably exceeded the usual cutoff of 2.0. However, since that time, hundreds of papers have tried to explain the cross-section of expected returns. Given the known number of factors that have been tried and the reasonable assumption that many more factors have been tried but did not make it to publication, the usual cutoff levels for statistical significance are not appropriate. Following recent work in the statistics literature, we present a framework that allows for multiple tests and derives recommended statistical significance levels for current research in asset pricing.

We begin with 311 papers that study cross-sectional return patterns published in a selection of journals. We provide recommended p-values from the first empirical tests in 1967 through to present day. We also project minimum t-ratios through 2032 assuming the rate of "factor production" remains similar to the recent experience. We present a taxonomy of historical factors as well as definitions.<sup>1</sup>

Our research is related to a recent paper by McLean and Pontiff (2013) who argue that certain stock market anomalies are less anomalous after being published.<sup>2</sup> Their paper tests the statistical biases emphasized in Leamer (1978), Ross (1989), Lo and MacKinlay (1990), Fama (1991) and Schwert (2003).

Our paper also adds to the recent literature on biases and inefficiencies in cross-sectional regression studies. Lewellen, Nagel and Shanken (2010) critique the usual practice of using cross-sectional  $R^2$ s and pricing errors to judge the success of a work and show that the explanatory powers of many previously documented factors are spurious.<sup>3</sup> Balduzzi and Robotti (2008) challenge the traditional approach of estimating factor risk premia via cross-sectional regressions and advocate a factor projection approach. Our work focuses on evaluating the statistical significance of a factor given the previous tests on other factors. Our goal is to use a multiple testing framework to both re-evaluate past research and to provide a new benchmark for current and future research.

There are limitations to our framework. First, should all factor discoveries be treated equally? We think no. A factor derived from a theory should have a lower hurdle than a factor discovered from a purely empirical exercise. Nevertheless, whether

<sup>&</sup>lt;sup>1</sup>We also provide a link to a file with full references and hyperlinks to the original articles: http://faculty.fuqua.duke.edu/~charvey/Factor-List.xlsx.

<sup>&</sup>lt;sup>2</sup>Other recent papers that systematically study the cross-sectional return patterns include Subrahmanyam (2010), Green, Hand and Zhang (2012, 2013).

 $<sup>^3</sup>$ A related work by Daniel and Titman (2012) constructs more powerful statistical tests and rejects several recently proposed factor models.

suggested by theory or empirical work, a t-ratio of 2.0 is too low. Second, our tests focus on unconditional tests. It is possible that a particular factor is very important in certain economic environments and not important in other environments. The unconditional test might conclude the factor is marginal. These two caveats need to be taken into account when using our recommended significance levels for current asset pricing research.

While our focus is on cross-sectional return patterns, our message applies to many different areas of finance. For instance, Frank and Goyal (2009) investigate around 30 variables that have been documented to explain capital structure decisions of public firms. Welch and Goyal (2004) examine the performance of a dozen variables that have been shown to predict market excess returns. These two applications are ideal settings to employ multiple testing methods.<sup>4</sup>

Our paper is organized as follows. In the second section, we provide a chronology of the "discovered" factors. The third section presents a categorization of the factors. Next, we introduce some multiple testing frameworks and suggest appropriate cutoffs for both past and future asset pricing tests. Some concluding remarks are offered in the final section.

# 2 The Search Process

Our goal is not to catalogue every asset pricing paper ever published. We narrow the focus to papers that propose and test new factors. For example, Sharpe (1964), Lintner (1965) and Mossin (1966) all theoretically proposed (at roughly the same time), a single factor model — the Capital Asset Pricing Model (CAPM). Beginning with Black, Jensen and Scholes (1972), there are hundreds of papers that test the CAPM. We include the theoretical papers as well as the first paper to empirically test the model, in this case, Black, Jensen and Scholes (1972). We do not include the hundreds of papers that test the CAPM in different contexts, e.g., international markets, different time periods. We do, however, include papers, such as Fama and MacBeth (1973) which tests the market factor as well as two additional factors.

Sometimes different papers propose different empirical proxies for the same type of economic risk. Although they may look similar from a theoretical standpoint, we still include them. An example is the empirical proxies for idiosyncratic financial constraints risk. While Lamont, Polk and Saa-Requejo (2001) use the Kaplan and Zingales (1997) index to proxy for firm-level financial constraint, Whited and Wu (2006) estimate their own constraint index based on the first order conditions of firms' optimization problem. We include both even though they are likely highly correlated.

Since our focus is on factors that can broadly explain asset market return patterns, we omit papers that focus on a small group of stocks or for a short period of time.

 $<sup>^4</sup>$ Harvey and Liu (2013) show how to adjust Sharpe Ratios used in performance evaluation for multiple tests.

This will, for example, exclude a substantial amount of empirical corporate finance research that studies event-driven return movements.<sup>5</sup>

Theoretical models sometimes lack immediate empirical content. Although they could be empirically relevant once suitable proxies are constructed, we choose to exclude them.

With these rules in mind, we narrow our search to generally the top journals in finance, economics and accounting. To include the most recent research, we search for working papers on SSRN. Working papers pose a challenge because there are thousands of them and they are not refereed. We choose a subset of papers that we suspect are in review at top journals or have been presented at top conferences or are due to be presented at top conferences. We end up using 62 working papers. In total, we focus on 311 published works and selected working papers. We catalogue 314 different factors.<sup>6</sup>

Our collection of 314 factors likely under-represents the factor population. First, we generally only consider top journals. Second, we are very selective in choosing only a handful of working papers. Third, and perhaps most importantly, we should be measuring the number of factors tested (which is unobservable) — that is, we do not observe the factors that were tested but failed to pass the usual significance levels and were never published (see Fama (1991)).

# 3 Factor Taxonomy

To facilitate our analysis, we group the factors into different categories. We start with two broad categories: "common" and "individual". "Common" means the factor can be viewed as a proxy for a common source of risk. Risk exposure to this factor or its innovations is supposed to help explain cross-sectional return patterns. "Individual" means the factor is specific to the security or portfolio. A good example is Fama and MacBeth (1973). While the beta against the market return is systematic (exposure to a common risk factor), the standard deviation of the market model residual is security specific and hence an idiosyncratic or individual risk. Many of the individual factors we identify are referred to in the literature as "characteristics".

Based on the unique properties of the proposed factors, we further divide the "common" and "individual" groups into finer categories. In particular, we divide "common" into: "financial", "macro", "microstructure", "behavioral", "accounting" and "other". We divide "individual" into the same categories — except we omit the "macro" classification, which is common, by definition. The following table provides further details on the definitions of these sub-categories and gives examples for each.

<sup>&</sup>lt;sup>5</sup>See McLean and Pontiff (2013) for an investigation of anomalies.

<sup>&</sup>lt;sup>6</sup>As already mentioned, some of these factors are highly correlated. For example, we include at least two versions of idiosyncratic volatility — where the residual is defined by different time-series regressions.

# 4 Adjusted T-ratios in Multiple Testing

# 4.1 Why Multiple Testing?

Given so many papers have attempted to explain the same cross-section of expected returns,<sup>7</sup> statistical inference should not be based on a "single" test perspective. Our goal is to provide guidance as to the appropriate significance level using a multiple testing framework.

We want to emphasize that there are many forces that make our guidance conservative, that is, a credible case can be made for even lower p-values. We have already mentioned that we only sample a subset of research papers and the "publication bias" issue (i.e. it is difficult to publish a non-result). However, there is another publication bias that is more subtle. In many scientific fields, replication studies routinely appear in top journals. That is, a factor is discovered, and others try to replicate it. In finance and economics, it is very difficult to publish replication studies. Hence, there is a bias towards publishing "new" factors rather than rigorously verifying the existence of discovered factors.

There are two ways to deal with the bias introduced by multiple testing: out-of-sample validation and using a statistical framework that allows for multiple testing. <sup>10</sup> When feasible, out-of-sample testing is the cleanest way to rule out spurious factors. In their study of anomalies, McLean and Pontiff take the out-of-sample approach. Their results show a degradation of performance of identified anomalies after publication which is consistent with the statistical bias. It is possible that this degradation is larger than they document. In particular, they drop 10 of their 82 anomalies because they could not replicate the in-sample performance of published studies. <sup>11</sup> Given these non-replicable anomalies were not even able to survive data revisions, they are likely to be insignificant strategies, either in-sample or out-of-sample. The degradation from the original published "alpha" is 100% for these strategies — which would lead to a higher average rate of degradation for the 82 strategies.

While the out-of-sample approach has many strengths, it has one important drawback: it cannot be used in real time. In contrast to many tests in the physical sciences,

<sup>&</sup>lt;sup>7</sup>Strictly speaking, different papers study different sample periods and hence focus on "different" cross-sections of expected returns. However, the bulk of the papers we consider have substantial overlapping sample periods. Also, if one believes that cross-sectional return patterns are stationary, then these papers are studying roughly the same cross-section of expected returns.

<sup>&</sup>lt;sup>8</sup>The literature on publication bias is voluminous. See Rosenthal (1979) for one of the earliest and most influential works on publication bias.

<sup>&</sup>lt;sup>9</sup>While the equity data is the same, it is often difficult to reconstruct certain factors and few papers post their datasets and computer programs.

<sup>&</sup>lt;sup>10</sup>Another approach to test factor robustness is to look at multiple asset classes. This approach has been followed in several recent papers, e.g., Frazzini and Pedersen (2012) and Koijen, Moskowitz, Pedersen and Vrugt (2012).

 $<sup>^{11}\</sup>mathrm{McLean}$  and Pontiff (2013) omit non-replicable strategies to obtain a well-defined ratio between in-sample and out-of-sample mean returns.

we often need years of data to do an out-of-sample test. We pursue the multiple testing framework because it yields immediate guidance on whether a discovered factor is real.

# 4.2 A Multiple Testing Framework

In statistics, multiple testing refers to simultaneous testing more than one hypothesis. The statistics literature was aware of this multiplicity problem at least 50 years ago.<sup>12</sup> Early generations of multiple testing procedures focus on the control of the family-wise error rate (see Section 4.3.1). More recently, increasing interest in multiple testing from the medical literature has spurred the development of methods that control the false-discovery rate (see Section 4.3.2). Nowadays, multiple testing is an active research area in both the statistics and the medical literature.<sup>13</sup>

Despite the rapid development of multiple testing methods, they have not attracted much attention in the finance literature.<sup>14</sup> Moreover, most of the research that does involve multiple testing focuses on the Bonferroni adjustment, which is known to be stringent. Our paper aims to fill this gap by systematically introducing the multiple testing framework.

First, we introduce a hypothetical example to motivate a more general framework. In Table 2, we categorize the possible outcomes of a multiple testing exercise. Panel A displays an example of what the literature could have discovered and Panel B notationalizes Panel A to ease our subsequent definition of the general Type I error rate — the chance of making at least one false discovery or the expected fraction of false discoveries.

Our example in Panel A assumes 100 published factors (denoted as R). Among these factors, suppose 50 are false discoveries and the rest are real ones. In addition,

<sup>&</sup>lt;sup>12</sup>For early research on multiple testing, see Scheffé's method (Scheffé (1959)) for adjusting significance levels in a multiple regression context and Tukey's range test (Tukey (1977)) on pairwise mean differences.

<sup>&</sup>lt;sup>13</sup>See Shaffer (1995) for a review of multiple testing procedures that control for the *family-wise* error rate. See Farcomeni (2008) for a review that focuses on procedures that control the *false-discovery rate* 

<sup>&</sup>lt;sup>14</sup>For the literature on multiple testing corrections for data snooping biases, see Sullivan, Timmermann and White (1999, 2001) and White (2000). For research on data snooping and variable selection in predictive regressions, see Foster, Smith and Whaley (1997) and Lynch and Vital-Ahuja (2012). For applications of Bonferroni's approach in the finance literature, see for example Shanken (1990), Ferson and Harvey (1999), Boudoukh et al. (2007) and Patton and Timmermann (2010). More recently, the *false discovery rate* and its extensions have been used to study technical trading and mutual fund performance, see for example Barras, Scaillet and Wermers (2010), Bajgrowicz and Scaillet (2012) and Kosowski, Timmermann, White and Wermers (2006). Conrad, Cooper and Kaul (2003) point out that data snooping accounts for a large proportion of the return differential between equity portfolios that are sorted by firm characteristics. Holland, Basu and Sun (2010) emphasize the importance of multiple testing in accounting research.

researchers have tried 600 other factors but none of them were found to be significant. Among them, 500 are truly insignificant but the other 100 are true factors. The total number of tests (M) is 700. Two types of mistakes are made in this process: 50 factors are falsely discovered to be true while 100 true factors are buried in unpublished work. Usual statistical control in a multiple testing context aims at reducing "50" or "50/100", the absolute or proportionate occurrence of false discoveries, respectively. Of course, we only observe published factors because factors that are tried and found to be insignificant rarely make it to publication. This poses a challenge since usual statistical techniques only handle the case where all testing results are observable.

Panel B defines the corresponding terms in a formal statistical testing framework. In a factor testing exercise, the typical null hypothesis is that a factor is not significant. Therefore, a factor is insignificant means the null hypothesis is "true". Using "0" ("1") to indicate the null is true (false) and "a" ("r") to indicate acceptance (rejection), we can easily summarize Panel A. For instance,  $N_{0|r}$  measures the number of rejections when the null is true (i.e. the number of false discoveries) and  $N_{1|a}$  measures the number of acceptances when the null is false (i.e. the number of missed discoveries). To avoid confusion, we try not to use standard statistical language in describing our notation but rather words unique to our factor testing context. The generic notation in Panel B is convenient for us to formally define different types of Type I errors and describe adjustment procedures in subsequent sections.

Table 2: Contingency Table in Testing M Hypotheses.

Panel A shows a hypothetical example for factor testing. Panel B presents the corresponding notation in a standard multiple testing framework.

<sup>&</sup>lt;sup>15</sup>Examples of publication of unsuccessful factors include Fama and MacBeth (1973) and Ferson and Harvey (1993). Fama and MacBeth (1973) show that squared beta and standard deviation of the market model residual have an insignificant role in explaining the cross-section of expected returns. Overall, it is rare to publish "non-results" and all instances of published non-results are coupled with significant results for other factors.

# 4.3 Type I Error

For a single hypothesis test, a value  $\alpha$  is used to control Type I error: the probability of finding a factor to be significant when it is not. In a multiple testing framework, restricting each individual test's Type I error rate at  $\alpha$  is not enough to control the overall probability of false discoveries. The intuition is that, under the null that all factors are insignificant, it is very likely for an event with  $\alpha$  probability to occur when many factors are tested. In multiple hypothesis testing, we need measures of the Type I error that help us simultaneously evaluate the outcomes of many individual tests.

To gain some intuition on plausible measures of Type I error, we return to Panel B of Table 2.  $N_{0|r}$  and  $N_{1|a}$  count the total number of the two types of errors:  $N_{0|r}$  counts false discoveries while  $N_{1|a}$  counts missed discoveries. As generalized from single hypothesis testing, the Type I error in multiple hypothesis testing should also be related to false discoveries — concluding a factor is "significant" when it is not. But, by definition, we must draw several conclusions in multiple hypothesis testing, and there is a possible false discovery for each. Therefore, plausible definitions of the Type I error should take into account the joint occurrence of false discoveries.

The literature has adopted at least two ways of summarizing the "joint occurrence". One way is to think about the total number of occurrences  $N_{0|r}$ .  $N_{0|r}$  greater than zero suggests incorrect statistical inference for the overall multiple testing problem — the occurrence of which we should limit. Therefore, the probability of event  $N_{0|r} > 0$  should be a meaningful quantity for us to control. Indeed, this is the intuition behind the family-wise error rate introduced later. On the other hand, when the total number of discoveries R is large, one or even a few false discoveries may be tolerable. In this case,  $N_{0|r}$  is no longer a suitable measure; a certain false discovery proportion may be more desirable. Unsurprisingly, the expected value of  $N_{0|r}/R$  is the focus of false discovery rate, the second type of control.

The two aforementioned measures are the most widely used in the statistics literature. Moreover, many other techniques can be viewed as extensions of these measures. <sup>16</sup> We now describe each measure in detail.

## 4.3.1 Family-wise Error Rate

The family-wise error rate (FWER) is the probability of at least one Type I error:

$$FWER = Pr(N_{0|r} \ge 1).$$

<sup>&</sup>lt;sup>16</sup>Holm (1979) is the first to formally define the family-wise error rate. Benjamini and Hochberg (1995) define and study the false discovery rate. Alternative definitions of error rate include per comparison error rate (Saville, 1990), positive false discovery rate (Storey, 2003) and generalized false discovery rate (Sarkar and Guo, 2009).

FWER measures the probability of even a single false discovery, irrespective of the total number of tests. For instance, researchers might test 100 factors; FWER measures the probability of incorrectly identifying one or more factors to be significant. Given significance or threshold level  $\alpha$ , we explore two existing methods (Bonferroni and Holm's adjustment) to ensure FWER does not exceed  $\alpha$ . Even as the number of trials increases, FWER still measures the probability of a single false discovery. This absolute control is in contrast to the proportionate control afforded by the *false discovery rate* (FDR), defined below.

### 4.3.2 False Discovery Rate

The false discovery proportion (FDP) is the proportion of Type I errors:

$$FDP = \begin{cases} \frac{N_{0|r}}{R} & \text{if } R > 0, \\ 0 & \text{if } R = 0. \end{cases}$$

The false discovery rate (FDR) is defined as:

$$FDR = E[FDP].$$

FDR measures the expected proportion of false discoveries among all discoveries. It is less stringent than FWER and usually much less so when many tests are performed.<sup>17</sup> Intuitively, this is because FDR allows  $N_{0|r}$  to grow in proportion to R whereas FWER measures the probability of making even a single Type I error.

Returning to Example A, Panel A shows that a false discovery event has occurred under FWER since  $N_{0|r} = 50 \ge 1$  and the realized FDP is high, 50/100 = 50%. This suggests that the *probability* of false discoveries (FWER) and the *expected* proportion

$$\begin{aligned} \text{FDR} &= E[\frac{N_{0|r}}{R}|R>0]Pr(R>0) \\ &\leq E[I_{(N_{0|r}\geq 1)}|R>0]Pr(R>0) \\ &= Pr((N_{0|r}\geq 1)\cap (R>0)) \\ &\leq Pr(N_{0|r}\geq 1) = \text{FWER}, \end{aligned}$$

where  $I_{(N_0|_r \ge 1)}$  is an indicator function of event  $N_0|_r \ge 1$ . This implies that procedures that control FWER under a certain significance level automatically control FDR under the same significance level. In our context, a factor discovery criterion that controls FWER at  $\alpha$  also controls FDR at  $\alpha$ .

<sup>&</sup>lt;sup>17</sup>There is a natural ordering between FDR and FWER. Theoretically, FDR is always bounded above by FWER, i.e.,  $FDR \le FWER$ . To see this, by definition,

of false discoveries (FDR) may be high.<sup>18</sup> The remedy, as suggested by many FWER and FDR adjustment procedures, would be to lower p-value thresholds for these hypotheses. In terms of Panel A, this would turn some of the 50 false discoveries insignificant and push them into the "Unpublished" category. Hopefully the 50 true discoveries would survive this p-value "upgrade" and remain significant, which is only possible if their p-values are relatively large.

On the other hand, Type II errors — the mistake of missing true factors — are also important in multiple hypothesis testing. Similar to Type I errors, both the total number of missed discoveries  $N_{1|a}$  and the fraction of missed discoveries among all abandoned tests  $N_{1|a}/(M-R)$  are frequently used to measure the severity of Type II errors. <sup>19</sup> Ideally, one would like to simultaneously minimize the chance of committing a Type I error and that of committing a Type II error. In our context, we would like to include as few insignificant factors (i.e., as low a Type I error rate) as possible and simultaneously as many significant ones (i.e., as low a Type II error rate) as possible. Unfortunately, this is not feasible: as in single hypothesis testing, a decrease in the Type I error rate often leads to an increase in the Type II error rate and vice versa. We therefore seek a balance between the two types of errors. A standard approach is to specify a significance level  $\alpha$  for the Type I error rate and derive testing procedures that aim to minimize the Type II error rate, i.e., maximize power, among the class of tests with Type I error rate at most  $\alpha$ .

When comparing two testing procedures that can both achieve a significance level  $\alpha$ , it seems reasonable to use their Type II error rates. However, the exact Type II error rate typically depends on a set of unknown parameters and is therefore difficult to assess.<sup>20</sup> To overcome this difficulty, researchers frequently use distance of the actual Type I error rate to some pre-specified significance level as the measure for a procedure's efficiency or power. Intuitively, if a procedure's actual Type I error rate is strictly below  $\alpha$ , we can probably push this error rate closer to  $\alpha$  by making the testing procedure less stringent, i.e., higher p-value threshold so there will be more discoveries. In doing so, the Type II error rate is presumably lowered given the inverse relation between the two types of error rates. Therefore, once a procedure's

<sup>&</sup>lt;sup>18</sup>Panel A only shows one realization of the testing outcome for a certain testing procedure (e.g., independent tests). To evaluate FWER and FDR, both of which are expectations and hence depend on the underlying joint distribution of the testing statistics, we need to know the population of the testing outcomes. To give an example that is compatible with Example A, we assume that the t-statistics for the 700 hypotheses are independent. Moreover, we assume the t-statistic for a true factor follows a normal distribution with mean zero and variance one, i.e.,  $\mathcal{N}(0,1)$ ; for a false factor, we assume its t-statistic follows  $\mathcal{N}(2,1)$ . Under these assumptions about the joint distribution of the test statistics, we find via simulations that FWER is 100% and FDR is 26%, both exceeding 5%.

<sup>&</sup>lt;sup>19</sup>See Simes (1986) for one example of Type II error in simulation studies and Farcomeni (2008) for another example in medical experiments.

<sup>&</sup>lt;sup>20</sup>In single hypothesis testing, a typical Type II error rate is a function of the realization of the alternative hypothesis. Since it depends on unknown parameter values in the alternative hypothesis, it is difficult to measure directly. The situation is exacerbated in multiple hypothesis testing because the Type II error rate now depends on a multi-dimensional unknown parameter vector. See Zehetmayer and Posch (2010) for power estimation in large-scale multiple testing problems.

actual Type I error rate falls below a pre-specified significance level, we want it to be as close as possible to that significance level in order to achieve the smallest Type II error rate. Ideally, we would like a procedure's actual Type I error rate to be exactly the same as the given significance level.

Both FWER and FDR are important concepts that have wide applications in many scientific fields.<sup>21</sup> However, based on specific applications, one may be preferred over the other. When the number of tests is very large, FWER controlling procedures tend to become very tough and eventually lead to a very limited number of discoveries, if any. Conversely, FWER control is more desirable when the number of tests is relatively small, in which case more discoveries can be achieved and at the same time trusted. In the context of our paper, it is difficult to judge whether the number of tests in the finance literature is large. First, we are unsure of the true number of factors that have been tried. Although there are around 200 published ones, hundreds or even thousands of factors might have been constructed and tested. Second, 200 may seem a large number to researchers in finance but is very small compared to the number of tests conducted in medical research.<sup>22</sup> Given this difficulty, we do not take a stand on the relative appropriateness of these two measures but instead provide adjusted p-values for both. Researchers can compare their p-values with these benchmarks to see whether FDR or even FWER is satisfied.

# 4.4 P-value Adjustment: Three Approaches

The statistics literature has developed many methods to control both FWER and FDR.<sup>23</sup> We choose to present the three most well-known adjustments: Bonferroni, Holm, and Benjamini, Hochberg and Yekutieli (BHY). Both Bonferroni and Holm control FWER, and BHY controls FDR. Depending on how the adjustment is implemented, they can be categorized into two general types of corrections: a "Single step" correction equally adjusts each p-value and a "sequential" correction is an adaptive procedure that depends on the entire distribution of p-values. Bonferroni is a single-step procedure whereas Holm and BHY are sequential procedures. Table 3 summarizes the two properties of the three methods.

In the usual multiple testing framework, we observe the outcomes of all test statistics, those rejected as well as not rejected. In our context, however, successful factors are more likely to be published and their p-values observed. This missing observations problem is the main obstacle in applying existing adjustment procedures. In appendix A, we propose a new general methodology to overcome this problem. For

<sup>&</sup>lt;sup>22</sup>For instance, tens of thousands of tests are performed in the analysis of DNA microarrays. See Farcomeni (2008) for more applications of multiple testing in medical research.

<sup>&</sup>lt;sup>23</sup>Methods that control FWER include Holm (1979), Hochberg (1988) and Hommel (1988). Methods that control FDR include Benjamini and Hochberg(1995), Benjamini and Liu (1999) and Benjamini and Yekutieli (2001).

now, we assume that all tests and their associated p-values are observed and detail the steps for the three types of adjustments.

Suppose there are in total M tests and we choose to set FWER at  $\alpha_w$  and FDR at  $\alpha_d$ . In particular, we consider an example with the total number of tests M=10 to illustrate how different adjustment procedures work. For our main results, we set  $\alpha_w$  at 5% and  $\alpha_d$  at 1%.<sup>24</sup> Table 4, Panel A lists the t-ratios and the corresponding p-values for 10 hypothetical tests. The numbers in the table are broadly consistent with the magnitude of t-ratios that researchers report for factor significance. Note that all 10 factors will be "discovered" if we test one hypothesis at a time. Multiple testing adjustments will usually generate different results.

### 4.4.1 Bonferroni's Adjustment

Bonferroni's adjustment is as follows:

• Reject any hypothesis with p-value  $\leq \frac{\alpha_w}{M}$ :

$$p_i^{Bonferroni} = \min[Mp_i, 1].$$

Bonferroni applies the same adjustment to each test. It inflates the original p-value by the number of tests M; the adjusted p-value is compared with the threshold value  $\alpha_w$ .

**Example 4.4.1** To apply Bonferroni's adjustment to the example in Table 4, we simply multiply all the p-values by 10 and compare the new p-values with  $\alpha_w = 5\%$ . Equivalently, we can look at the original p-values and consider the cutoff of  $0.5\% (= \alpha_w/10)$ . This leaves the t-ratio of tests 4,6,7,8 and 9 as significant.

<sup>&</sup>lt;sup>24</sup>Our choice of making  $\alpha_d$  smaller than  $\alpha_w$  is deliberate. See discussion in Section 4.6. In addition, we show how our results change depending on the value of  $\alpha_d$ .

## Table 4: An Example of Multiple Testing

Panel A displays 10 t-ratios and their associated p-values for a hypothetical example. Panel B and C explain Holm's and BHY's adjustment procedure, respectively. Bold numbers in each panel are associated with significant factors under the specific adjustment procedure of that panel. M represents the total number of tests (10) and  $c(M) = \sum_{j=1}^{M} 1/j$ . k is the order of p-values from lowest to highest.  $\alpha_w$  is the significance level for Bonferroni's and Holm's procedure and  $\alpha_d$  is the significance level for BHY's procedure. The threshold t-ratio for Bonferroni is 0.05% ( $\alpha_w = 5\%$ ), for Holm 0.85% ( $\alpha_w = 5\%$ ) and for BHY 0.09% ( $\alpha_d = 1\%$ ) or 1.28% ( $\alpha_d = 5\%$ ).

Using the notation in Panel B of Table 2 and assuming  $M_0$  of the M null hypotheses are true, Bonferroni operates as a single step procedure that can be shown to restrict FWER at levels less than or equal to  $M_0\alpha_w/M$ , without any assumption on the dependence structure of the p-values. Since  $M_0 \leq M$ , Bonferroni also controls FWER at level  $\alpha_w$ .<sup>25</sup>

## 4.4.2 Holm's Adjustment

*Holm*'s adjustment is as follows:

 $<sup>^{25}</sup>$ The number of true nulls  $M_0$  is inherently unknown, so we usually cannot make Bonferroni more powerful by increasing  $\alpha_w$  to  $\hat{\alpha} = M\alpha_w/M_0$  (note that  $M_0\hat{\alpha}/M = \alpha_w$ ). However some papers, including Schweder and Spjotvoll (1982) and Hochberg and Benjamini (1990), try to improve the power of Bonferroni by estimating  $M_0$ . We try to achieve the same goal by using either Holm's procedure which also controls FWER or procedures that control FDR, an alternative definition of Type I error rate.

- Order the original p-values such that  $p_{(1)} \leq p_{(2)} \leq \cdots p_{(k)} \leq \cdots \leq p_{(M)}$  and let associated null hypotheses be  $H_{(1)}, H_{(2)}, \cdots H_{(k)}, \cdots, H_{(M)}$ .
- Let k be the minimum index such that  $p_{(k)} > \frac{\alpha_w}{M+1-k}$ .
- Reject null hypotheses  $H_{(1)} \cdots H_{(k-1)}$  (i.e., declare these factors significant) but not  $H_{(k)} \cdots H_{(M)}$ .

The equivalent adjusted p-value is therefore

$$p_{(i)}^{Holm} = \min[\max_{j \le i} \{ (M - j + 1) p_{(j)} \}, 1].$$

Holm's adjustment is a step-up procedure: for the ordered p-values, we start from the smallest p-value and go up to the largest one. If k is the smallest index that satisfies  $p_{(k)} > \frac{\alpha_w}{M+1-k}$ , we will reject all tests whose ordered index is below k.

To explore how Holm's adjustment procedure works, suppose  $k_0$  is the smallest index such that  $p_{(k)} > \frac{\alpha_w}{M+1-k}$ . This means that for  $k < k_0$ ,  $p_{(k)} \le \frac{\alpha_w}{M+1-k}$ . In particular, for k=1, Bonferroni = Holm, i.e.,  $\frac{\alpha_w}{M} = \frac{\alpha_w}{M+1-(k=1)}$ ; for k=2,  $\frac{\alpha_w}{M} < \frac{\alpha_w}{M+1-(k=2)}$ , so Holm is less stringent than Bonferroni. Since less stringent hurdles are applied to the second to the  $(k_0-1)$ th p-values, more discoveries are generated under Holm's than Bonferroni's adjustment.

**Example 4.4.2** To apply Holm's adjustment to the example in Table 4, we first order the p-values in ascending order and try to locate the smallest index k that makes  $p_{(k)} > \frac{\alpha_w}{M+1-k}$ . Table 4, Panel B shows the ordered p-values and the associated  $\frac{\alpha_w}{M+1-k}$ 's. Starting from the smallest p-value and going up, we see that  $p_{(k)}$  is below  $\frac{\alpha_w}{M+1-k}$  until k=7, at which  $p_{(7)}$  is above  $\frac{\alpha_w}{10+1-7}$ . Therefore, the smallest k that satisfies  $p_{(k)} > \frac{\alpha_w}{M+1-k}$  is 7 and we reject the null hypothesis for the first six ordered tests (we discover six factors) and fail to reject the null for the remaining four tests. The original labels for the rejected tests are in the second row in Panel B. Compared to Bonferroni, one more factor (2) is discovered, that is, six factors rather than five are significant. In general, Holm's approach leads to more discoveries and all discoveries under BF are also discoveries under Holm's.

Like Bonferroni, Holm also restricts FWER at  $\alpha_w$  without any requirement on the dependence structure of p-values. It can also be shown that Holm is uniformly more powerful than Bonferroni in that tests rejected (factors discovered) under Bonferroni are always rejected under Holm but not vice versa. In other words, Holm leads to at least as many discoveries as Bonferroni. Given the dominance of Holm over Bonferroni, one might opt to only use Holm. We include Bonferroni because it is the most widely used adjustment and a simple single-step procedure.

## 4.4.3 Benjamini, Hochberg and Yekutieli's Adjustment

Benjamini, Hochberg and Yekutieli (BHY)'s adjustment is as follows:

- As with Holm's procedure, order the original p-values such that  $p_{(1)} \leq p_{(2)} \leq \cdots p_{(k)} \leq \cdots \leq p_{(M)}$  and let associated null hypotheses be  $H_{(1)}, H_{(2)}, \cdots H_{(k)}, \cdots, H_{(M)}$ .
- Let k be the maximum index such that  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$ .
- Reject null hypotheses  $H_{(1)} \cdots H_{(k)}$  but not  $H_{(k+1)} \cdots H_{(M)}$ .

The equivalent adjusted p-value is defined sequentially as:

$$p_{(i)}^{BHY} = \begin{cases} p_{(M)} & \text{if } i = M, \\ \min[p_{(i+1)}^{BHY}, \frac{M \times c(M)}{i} p_{(i)}] & \text{if } i \leq M - 1. \end{cases}$$

where, c(M) is a function of the total number of tests M and controls for the generality of the test. We adopt the choice in Benjamini and Yekutieli (2001) and set c(M) at

$$c(M) = \sum_{j=1}^{M} \frac{1}{j},$$

a value at which the procedure works under arbitrary dependence structure among the p-values. We discuss alternative specifications of c(M) shortly.

In contrast to Holm's, BHY's method starts with the largest p-value and goes down to the smallest one. If k is the largest index that satisfies  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$ , we will reject all tests (discover factors) whose ordered index is below or equal to k. Also, note that  $\alpha_d$  (significance level for FDR) is chosen to be a smaller number than  $\alpha_w$  (significance level for FWER). The reason for such a choice is discussed in Section 4.6.

To explore how BHY works, let  $k_0$  be the largest index such that  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$ . This means that for  $k > k_0$ ,  $p_{(k)} > \frac{k}{M \times c(M)} \alpha_d$ . In particular, we have  $p_{(k_0+1)} > \frac{(k_0+1)}{M \times c(M)} \alpha_d$ ,  $p_{(k_0+2)} > \frac{(k_0+2)}{M \times c(M)} \alpha_d$ , ...,  $p_{(M)} > \frac{M}{M \times c(M)} \alpha_d$ . We see that the  $(k_0+1)$ th to the last null hypotheses, not rejected, are compared to numbers smaller than  $\alpha_d$ , the usual significance level in single hypothesis testing. By being stricter than single hypothesis tests, BHY guarantees that the false discovery rate is below the prespecified significance level under arbitrary dependence structure among the p-values. See Benjamini and Yekutieli (2001) for details on the proof.

**Example 4.4.3** To apply BHY's adjustment to the example in Table 4, we first order the p-values in ascending order and try to locate the largest index k that satisfies

 $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$ . Table 4, Panel C shows the ordered p-values and the associated  $\frac{k}{M \times c(M)} \alpha_d$ 's. Starting from the largest p-value and going down, we see that  $p_{(k)}$  is above  $\frac{k}{M \times c(M)} \alpha_d$  until k = 4, at which  $p_{(4)}$  is below  $\frac{k}{10 \times 2.93} \alpha_d$ . Therefore, the smallest k that satisfies  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$  is 4 and we reject the null hypothesis for the first four ordered tests and fail to reject for the remaining six tests. In the end, BHY leads to four significant factors (7,8,4) and (7,8,4), one less than Bonferroni and two less than Holm. If we set  $\alpha_d$  at 5%, then BHY leads to seven significant factors (7,8,4,9,6,2) and (7,8,4,9,6,2) are

Under independence among p-values, we can gain insight into the choice of  $p_{(i)}^{BHY}$  by interpreting  $p_{(i)}^{BHY}$  as the solution to a post-experiment maximization problem.<sup>27</sup> In particular, assume all individual hypotheses are performed and their p-values collected. It can be shown that  $p_{(i)}^{BHY}$  is the solution to the following problem:

Objective: Choose  $\hat{p}$  that maximizes the number of discoveries  $n(\hat{p})$ , Constraint:  $\hat{p}M/n(\hat{p}) \leq \alpha_d$ .

We first interpret the constraint. Under independence and when each hypothesis is tested individually at level  $\hat{p}$ , the expected number of false discoveries satisfies  $E(N_{0|r}) \leq \hat{p}M$ . Hence, after observing the outcome of the experiment and thus conditional on having  $n(\hat{p})$  discoveries, the FDR is no greater than  $\hat{p}M/n(\hat{p})$ . The constraint therefore requires the post-experiment FDR to satisfy the pre-specified significance level. Under this constraint, the objective is to choose  $\hat{p}$  to maximize the number of discoveries. Since the constraint is satisfied for each realized p-value sequence of the experiment, it is satisfied in expectation as well. In sum,  $p_{(i)}^{BHY}$  is the optimal cutoff p-value (i.e., maximal number of discoveries) that satisfies the FDR constraint for each outcome of the experiment.

The choice of c(M) determines the generality of BHY's procedure. Intuitively, the larger c(M) is, the more difficult it is to satisfy the inequality  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$  and hence there will be fewer discoveries. This makes it easier to restrict the false discovery rate below a given significance level since fewer discoveries are made. In the original work that develops the concept of false discovery rate and related testing procedures, c(M) is set equal to one. It turns out that under this choice, BHY is only valid when the test statistics are independent or positively dependent.<sup>28</sup> With our

 $<sup>^{26}</sup>$  For independent tests, 10/10 factors are discovered. For BHY, the effective cutoff is 0.09% (1.28% if  $\alpha_d=5\%$ ), for Bonferroni 0.50% and for Holm 0.85%. The cutoffs are all far smaller than the usual 5%.

<sup>&</sup>lt;sup>27</sup>This interpretation is shown in Benjamini and Hochberg (1995). Under independence,  $c(M) \equiv 1$  is sufficient for BHY to work. See our subsequent discussions on the choice of c(M).

<sup>&</sup>lt;sup>28</sup>Benjamini and Hochberg (1995) is the original paper that proposes FDR and sets  $c(M) \equiv 1$ . They show their procedures restricts the FDR below the pre-specified significance level under independence. Benjamini and Yekutieli (2001) and Sarkar (2002) later show that the choice of  $c(M) \equiv 1$  also works under positive dependence. For recent studies that assume specific dependence structure to improve on BHY, see Yekutieli and Benjamini (1999), Troendle (2000), Dudoit and Van

choice of c(M), BHY is valid under any form of dependence among the p-values.<sup>29</sup> Note with c(M) > 1, this reduces the size of  $\frac{k}{M \times c(M)} \alpha_d$  and it is tougher to satisfy the inequality  $p_{(k)} \leq \frac{k}{M \times c(M)} \alpha_d$ . That is, there will be fewer factors found to be significant.

Figure 1 summarizes Example A. It plots the original p-value sample as well as threshold p-value lines for various adjustment procedures. We see the stark difference in outcomes between multiple and single hypothesis testing. While all 10 factors would be discovered under single hypothesis testing, only four to seven factors would be discovered under a multiple hypothesis test. Although single hypothesis testing

guarantees the Type I error of each test meets a given significance level, meeting the more stringent FWER or FDR bound will lead us to discard a number of factors.<sup>30</sup>

To summarize the properties of the three adjustment procedures, Bonferroni's adjustment is the simplest and inflates the original p-value by the total number of tests. Holm's adjustment is a refinement of Bonferroni but involves ordering of p-values and thus depends on the entire distribution of p-values. BHY's adjustment, unlike that of Bonferroni or Holm, aims to control the false discovery rate and also depends on the distribution of p-values. Importantly, all three methods allow for general dependence among the test statistics.

# 4.5 Summary Statistics

Figure 2 shows the history of discovered factors and publications.<sup>31</sup> We observe a dramatic increase in factor discoveries during the last decade. In the early period from 1980 to 1991, only about one factor is discovered per year. This number has grown to around five in the 1991-2003 period, during which a number of papers, such as Fama and French (1992), Carhart (1997) and Pastor and Stambaugh (2003), spurred interest in studying cross-sectional return patterns. In the last nine years, the annual factor discovery rate has increased sharply to around 18. In total, 162 factors were discovered in the past 9 years, roughly doubling the 90 factors discovered in all previous years. We do not include working papers in Figure 1. In our sample, there are 62 working papers covering 67 factors.

We obtain t-ratios for each of the 314 factors discovered, including the ones in working papers.<sup>32</sup> The overwhelming majority of t-ratios exceed the 1.96 benchmark for 5% significance.<sup>33</sup> The non-significant ones typically belong to papers that propose multiple factors. These likely represent only a small sub-sample of non-significant t-ratios for all tried factors. Importantly, we take these t-ratios as given. That is, we assume they are econometrically sound with respect to the usual suspects (data errors, coding errors, heteroskedasticity, autocorrelation, outliers, etc.).

<sup>&</sup>lt;sup>30</sup>Note with BHY ( $\alpha_d = 1\%$ ) with general dependence, 4 factors are discovered. With c(M) = 1 (independence), 5 are discovered.

<sup>&</sup>lt;sup>31</sup>To be specific, we only count those that have t-ratios or equivalent statistics reported. Roughly 20 new factors fail to satisfy this requirement. For details on these, see factors in Table 6 marked with ‡.

<sup>&</sup>lt;sup>32</sup>The sign of a t-ratio depends on the source of risk or the direction of the long/short strategy. We usually calculate p-values based on two-sided t-tests, so the sign does not matter. Therefore we use absolute value of these t-ratios.

 $<sup>^{33}</sup>$ The multiple testing framework is robust to outliers. The procedures are based on either the total number of tests (Bonferroni) or the order statistics of t-ratios (Holm and BHY). However, outliers may affect our results on truncated normal likelihood estimation when M>R (see Appendix A). For the results in the paper, we use the full sample. Appendix A shows the implications of trimming the top one percent of t-ratios.

# 4.6 P-value Adjustment When M = R

We now apply the three adjustment methods previously introduced to the observed factor tests, under the assumption that test results of all tried factors are available. This assumption is false since our sample under-represents all insignificant factors by conventional significance standards: we only observe those insignificant factors that are published alongside significant ones. We design methods to handle this missing data issue later.

Despite some limitations, our results in this section are useful for at least two purposes. First, the benchmark t-ratio based on our incomplete sample provides a lower bound of the true t-ratio benchmark. In other words, if M > R, then we would accept fewer factors than when  $M = R,^{34}$ , so future t-ratios need to at least surpass our benchmark to claim significance. Second, results in this section can be

 $<sup>^{34}</sup>$ This is always true for Bonferroni's adjustment but not always true for the other two types of adjustments. The Bonferroni adjusted t-ratio is monotonically increasing in the number of trials so

rationalized within a Bayesian or hierarchical testing framework.<sup>35</sup> Factors in our list constitute an "elite" group: they have survived academia's scrutiny for publication. Placing a high prior on this group in a Bayesian testing framework or viewing this group as a cluster in a hierarchical testing framework, one can interpret results in this section as the first step factor selection within an a priori group.

Based on our sample of observed t-ratios of published factors,<sup>36</sup> we obtain three benchmark t-ratios. In particular, at each point in time, we transform the set of available t-ratios into p-values. We then apply the three adjustment methods to obtain benchmark p-values. Finally, these p-value benchmarks are transformed back into t-ratios, assuming that standard normal distribution well approximates the t-distribution. To guide future research, we extrapolate our benchmark t-ratios twenty years into the future.

We choose to set  $\alpha_w$  at 5% and  $\alpha_d$  at 1% for our main results. Significance level is subjective, as in individual hypothesis testing where conventional significance levels are usually adopted. Since FWER is a special case of the Type I error in individual testing and 5% seems the default significance level in cross-sectional studies, we set  $\alpha_w$  at 5%. On the other hand, FDR is a weaker control relative to FWER; moreover, it has no power in further screening individual tests if FDR is set greater than or equal to the significance level of individual tests.<sup>37</sup> We therefore set FDR at 1% but will explain what happens when  $\alpha_d$  is increased to 5%.

Figure 3 presents the three benchmark t-ratios. Both Bonferroni and Holm adjusted benchmark t-ratios are monotonically increasing in the number of discoveries. For Bonferroni, the benchmark t-ratio starts at 1.96 and increases to 3.78 by 2012. It reaches 3.99 in 2032. The corresponding p-values for 3.78 and 3.99 are 0.02% and

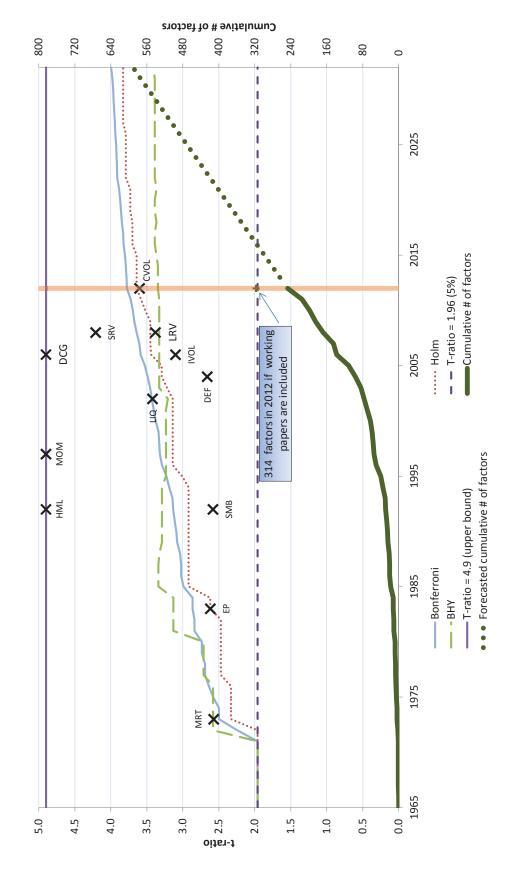

the t-ratio benchmark will only rise if there are more factors. Holm and BHY depend on the exact t-ratio distribution so more factors do not necessarily imply higher t-ratio benchmark.

<sup>35</sup>See Wagenmakers and Grünwald (2006) and Storey (2003) on Bayesian interpretations of traditional hypothesis testing. See Meinshausen (2008) for a hierarchical approach on variable selection.

<sup>36</sup>There are at least two ways to generate t-ratios for a risk factor. One way is to show that factor related sorting results in cross-sectional return patterns that are not explained by standard risk factors. The t-ratio for the intercept of the long/short strategy returns regressed on common risk factors is usually reported. The other way is to use factor loadings as explanatory variables and show that they are related to the cross-section of expected returns after controlling for standard risk factors. Individual stocks or stylized portfolios (e.g., Fama-French 25 portfolios) are used as dependent variables. The t-ratio for the factor risk premium is taken as the t-ratio for the factor. In sum, depending on where the new risk factor or factor returns enter the regressions, the first way can be thought of as the left hand side (LHS) approach and the second the right hand side (RHS) approach. For our data collection, we choose to use the RHS t-ratios. When they are not available, we use the LHS t-ratios or simply the t-ratios for the average returns of long/short strategies if the authors do not control for other risk factors.

<sup>37</sup>This is true for Benjamini and Hochberg (1995)'s original adjustment algorithm in which c(M) is set equal to one. Under this choice, the threshold for the largest p-value becomes  $\alpha_d$  in BHY's method. As a result, if all tests are individually significant at level  $\alpha_d$ , the largest p-value would satisfy  $p_{(M)} \leq \alpha_d$ . Based on BHY's procedure, this means we reject all null hypotheses. In our context, the p-values for significant factors are all below 5%. Therefore, under c(M) = 1, if we set  $\alpha_d$  equal to 5%, we would not be able to reject any of these significant factors.

The green solid curve shows the historical cumulative number of factors discovered, excluding those from working papers. Forecasts (dotted green line) are based on a linear extrapolation. The dark crosses mark selected factors proposed by the literature. They are Fama and French (1992)), MOM (momentum; Carhart (1997)), LIQ (liquidity; Pastor and Stambaugh (2003)), DEF (default likelihood; Vassalou and Xing (2004)), IVOL (idiosyncratic volatility; Ang, Hodrick, Xing and Zhang (2006)); DCG (durable consumption goods; MRT (market beta; Fama and MacBeth (1973)), EP (earnings-price ratio; Basu (1983)), SMB and HML (size and book-to-market; Yogo (2006)); SRV and LRV (short-run and long-run volatility; Adrian and Rosenberg (2008)) and CVOL (consumption volatility; Boguth and Kuehn (2012)). T-ratios over 4.9 are truncated at 4.9. For detailed descriptions of these factors, see Table 6. 0.01% respectively, much lower than the starting level of 5%. Holm implied t-ratios always fall below Bonferroni t-ratios, consistent with the fact that Bonferroni always results in fewer discoveries than Holm. However, Holm tracks Bonferroni closely and their difference is small. BHY implied benchmarks, on the other hand, are not monotonic. They fluctuate before year 2000 and stabilize at 3.38 after 2010. This stationarity feature of BHY implied t-ratios, inherent in the definition of FDR, is in contrast to Bonferroni and Holm. Intuitively, at any fixed significance level  $\alpha$ , the Law of Large Numbers forces the false discovery rate (FDR) to converge to a constant. If we change  $\alpha_d$  to 5%, the corresponding BHY implied benchmark t-ratio is 2.78 (p-value = 0.54%) in 2012 and 2.81 (p-value = 0.50%) in 2032, still much higher than the 1.96 staring value. In sum, taking into account of testing multiplicity, we believe the minimum threshold t-ratio for 5% significance is about 2.8, which corresponds to a p-value of 0.5%.

To see how the new t-ratio benchmarks better differentiate the statistical significance of factors, in Figure 3 we mark the t-ratios of a few prominent factors. Among these factors, HML, MOM, DCG, SRV and MRT are significant across all types of t-ratio adjustments, EP, LIQ and CVOL are sometimes significant and the rest are never significant.

### 4.7 Robustness

Our three adjustment methods are able to control their Type I error rates (FWER for Bonferroni and Holm; FDR for BHY) under arbitrary distributional assumptions about the test statistics. However, if the test statistics follow a certain dependence structure, then some of the three methods will be conservative in that too few factors are discovered. For instance, if the test statistics are positively correlated, then BHY tends to be conservative. Then again, counteracting this conservatism is our incomplete coverage of significant factors. By adding factors to our current sample, certain adjusted threshold t-ratios (e.g., Bonferroni) will increase, making our current estimates less conservative. We discuss the dependence issue in this section and address the incomplete coverage issue in the Appendix.

Note that our coverage of insignificant factors is even more "incomplete". In fact, we only include around 20 insignificant factors. We propose a simulation framework to handle this missing data issue below.

<sup>&</sup>lt;sup>38</sup>This intuition is precise for the case when tests are independent. When there is dependence, we need the dependence to be weak to apply the Law of Large Numbers.

## 4.7.1 Test statistics dependence

In theory, under independence, Bonferroni and Holm approximately achieve the prespecified significance level  $\alpha$  when the number of tests is large.<sup>39</sup> On the other hand, both procedures tend to generate fewer discoveries than desired when there is a certain degree of dependence among the tests. Intuitively, in the extreme case where all tests are the same, we do not need to adjust at all: FWER is the same as the Type I error rate for single tests. Hence, the usual single hypothesis test is sufficient. Under either independence or positive dependence, the actual Type I error rate of BHY is strictly less than the pre-specified significance level, i.e., BHY is stringent in that too few factors are discovered.<sup>40</sup>

Having discussed assumptions for the testing methods to work efficiently, we now try to think of scenarios that can potentially violate these assumptions. First, factors that proxy for the same type of risk may be dependent. Moreover, returns of longshort portfolios designed to achieve exposure to a particular type of factor may be correlated. For example, hedge portfolios based on dividend yield, earnings yield and book-to-market are correlated. Other examples include risk factors that reflect financial constraints risk, market-wide liquidity and uncertainty risk. If this type of positive dependence exists among test statistics, all three methods would likely to generate fewer significant factors than desired. There is definitely some dependence in our sample. As mentioned previously, there are a number of factors with price in the denominator which are naturally correlated. Another example is that we count four different idiosyncratic volatility factors. On the other hand, most often factors need to "stand their ground" to be publishable. In the end, if you think we are overcounting at 314, consider taking a haircut to 112 factors (the number of "common" factors). Figure 3 shows that our main conclusions do not materially change. For example, the Holm at 112 factors is 3.29 (p-value = 0.10%) while Holm at 314 factors is 3.64(p-value = 0.03%).

Second, research studying the same factor but based on different samples will generate highly dependent test statistics. Examples include the sequence of papers studying the size effect. We try to minimize this concern by including, with a few exceptions, only the original paper that proposes the factor. To the extent that our list includes few such duplicate factors, our method greatly reduces the dependence

$$FWER = Pr(N_{0|r} \ge 1)$$

$$= 1 - Pr(N_{0|r} = 0)$$

$$= 1 - (1 - \alpha/n)^n$$

$$\xrightarrow{n \to \infty} 1 - \exp(-\alpha) \approx \alpha$$

where n denotes the number of tests. The last step approximation is true when  $\alpha$  is small.

 $<sup>^{39}</sup>$ To see this for Bonferroni, suppose tests are independent and all null hypotheses are true. We have

<sup>&</sup>lt;sup>40</sup>See footnote 4.4.3 and the references therein.

that would be introduced by including all papers studying the same factor but for different sample periods.

#### 4.7.2 The Case When M > R

To deal with the missing data issue when M > R, we propose in Appendix A a simulation framework to estimate benchmark t-ratios. The idea is to first back out the underlying distribution for the t-statistics of all tried factors; then, to generate benchmark t-ratio estimates, apply the three adjustment procedures to simulated t-statistics samples.

Based on our estimates, 51% of all tried factors are missing. The new benchmark t-ratios for Bonferroni and Holm are estimated to be 3.83 and 3.72, respectively; both slightly higher than when M=R. This is as expected because more factors are tried under this framework. The BHY implied t-ratio increases from 3.34 to 3.44 at 1% significance and from 2.78 to 2.89 at 5% significance. In sum, across various scenarios, we think the minimum threshold t-ratio is 2.9, corresponding to BHY's adjustment for M>R at 5% significance. Alternative cases all result in even higher benchmark t-ratios. Please refer to Appendix A for the details.

### 4.7.3 A Bayesian Hypothesis Testing Framework

We can also study multiple hypothesis testing within a Bayesian framework. In Appendix B, we outline a standard Bayesian multiple hypothesis testing framework and explain its relevance to our factor testing problem. We discuss in detail the pros and cons of the Bayesian approach. In contrast to the frequentists approach, which uses generalized Type I error rates to guide multiple testing, the Bayesian approach relies on the posterior likelihood function and thus contains a natural penalty term for multiplicity. However, this simplicity comes at the expense of having a restrictive hierarchical model structure and independence assumptions that may not be realistic for our factor testing problem. Although extensions incorporating certain forms of dependence are possible, it is unclear what precisely we should do for the 314 factors in our list. In addition, even for the Bayesian approach, final reject/accept decision still involves threshold choice. Finally, as the number of tests becomes large, the Bayesian approach gets computationally challenging.<sup>42</sup> Due to these concerns, we choose not to implement the Bayesian approach and instead discuss it briefly. We

<sup>&</sup>lt;sup>41</sup>Two sets of results are shown in Appendix A: one based on the original sample and the other on the trimmed sample. We use results based on the trimmed sample as they provide the lower bounds on the benchmark t-ratios.

<sup>&</sup>lt;sup>42</sup>The calculation of the posterior likelihood function involves multiple integrals. As the number of tests becomes large, simulation approaches such as importance sampling may become unstable in calculating these high-dimensional integrals.

leave extensions of the basic Bayesian framework that could possibly alleviate the above concerns to future research.

# 5 Conclusion

At least 314 factors have been tested to explain the cross-section of expected returns. Most of these factors have been proposed over the last ten years. Indeed, Cochrane (2011) refers to this as "a zoo of new factors". Our paper argues that it is a serious mistake to use the usual statistical significance cutoffs (e.g., a t-ratio exceeding 2.0) in asset pricing tests. Given the plethora of factors and the inevitable data mining, many of the historically discovered factors would be deemed "significant" by chance.

Our paper presents three different multiple testing frameworks. While these frameworks differ in their assumptions, they are consistent in their conclusions. We argue that a newly discovered factor today should have a t-ratio that exceeds 3.0. We provide a time-series of recommended "cutoffs" from the first empirical test in 1967 through to present day. Many published factors fail to exceed our recommended cutoffs.

While a ratio of 3.0 (which corresponds to a p-value of 0.27%) seems like a very high hurdle, we also argue that there are good reasons to expect that 3.0 is too low. First, we only count factors that are published in prominent journals and we sample only a small fraction of the working papers. Second, there are surely many factors that were tried by empiricists, failed, and never made it to publication or even a working paper. Indeed, the culture in financial economics is to focus on the discovery of new factors. In contrast to other fields such as medical science, it is rare to publish replication studies of existing factors. Given that our count of 314 tested factors is surely too low, this means the t-ratio cutoff is likely even higher.<sup>43</sup>

Should a t-ratio of 3.0 be used for every factor proposed in the future? Probably not. A case can be made that a factor developed from first principles should have a lower threshold t-ratio than a factor that is discovered as a purely empirical exercise. Nevertheless, a t-ratio of 2.0 is no longer appropriate — even for factors that are derived from theory.

In medical research, the recognition of the multiple testing problem has led to the disturbing conclusion that "most claimed research findings are false" (Ioannidis (2005)). Our analysis of factor discoveries leads to the same conclusion – many of the factors discovered in the field of finance are likely false discoveries: of the 294 published significant factors, 158 are false discoveries under Bonferonni, 142 under

<sup>&</sup>lt;sup>43</sup>In astronomy and physics, even higher threshold t-ratios are often used to control for testing multiplicity. For instance, the vigorously debated discovery of Higgs Boson has a t-ratio of more than 5 (p-value less than 0.0001%). See ATLAS Collaboration (2012) and CMS Collaboration (2012).

Holm, 132 under BHY (1%) and 80 under BHY (5%). In addition, the idea that there are so many factors is inconsistent with the factor analysis evidence, where, perhaps there are five "statistical" common factors driving time-series variation in equity returns (Ahn, Horenstein and Wang (2012)).

The assumption that researchers follow the rules of classical statistics (e.g., randomization, unbiased reporting, etc.) is at odds with the notion of individual incentives which, ironically, is one of the fundamental premises in economics. Importantly, the optimal amount of data mining is not zero since some data mining produces knowledge. The key, as argued by Glaeser (2008), is to design appropriate statistical methods to adjust for biases, not to eliminate research initiatives. The multiple testing framework detailed in our paper is true to this advice.

Our research quantifies the warnings of both Fama (1991) and Schwert (2003). We attempt to navigate the zoo and establish new benchmarks to guide empirical asset pricing tests.

Notes to Table

This table contains a summary of risk factors that explain the cross-section of expected returns. The column "Indi.(#)" ("Common(#)") reports the cumulative number of empirical factors that are classified as individual (common) risk factors.

\*: insignificant; †: duplicated; ‡: missing p-value.

a: No p-values reported for their factors constructed from principal component analysis.

b: Fama and French (1992) create zero-investment portfolios to test size and book-to-market effects. This is different from the testing approach in Banz (1981). We therefore count Fama and French (1992)'s test on size effect as a separate one.

c: No p-values reported for their high order equity index return factors.

d: No p-values reported for their eight risk factors that explain international equity returns.

e: No p-values reported for his high order return factors.

f: No p-values reported for their five hedge fund style return factors.

g: Vanden (2004) reports a t-statistic for each Fama-French 25 size and book-to-market sorted stock portfolios. We average these 25 t-statistics.

h: Acharya and Pedersen (2005) consider the illiquidity measure in Amihud (2002). This is different from the liquidity measure in Pastor and Stambaugh (2003). We therefore

i: No p-values reported for the interactions between market return and option returns.

j: No p-values reported for their co-moment betas.

k: No p-values reported for his distress tracking factor.

I: Gomez, Priestley and Zapatero (2012) study census division level labor income. However, most of the division level labor income have a non-significant t-statistic. We do

m: No p-values reported for their factors estimated from the long-run risk model.

## A Multiple Testing When M is Unknown

The empirical difficulty in applying standard p-value adjustments is that we do not observe factors that have been tried, found to be insignificant and then discarded. We attempt to overcome this difficulty using a simulation framework. The idea is first simulate the empirical distribution of p-values for all experiments (published and unpublished) and then adjust p-values based on these simulated samples.

First, we assume the test statistic (t-statistic, for instance) for any experiment follows a certain distribution F (e.g., log-normal distribution) and the set of published works is a truncated F distribution. Based on the estimation framework for truncated distributions, <sup>44</sup> we estimate parameters of distribution F and total number of trials M. Next we simulate many sequences of p-values, each corresponding to a plausible set of p-value realizations of all trials. To account for the uncertainty in parameter estimates of F and M, we simulate p-value sequences based on the distribution of estimated F and F are all p-values. The median is taken as the final adjusted p-value.

# A.1 Using Truncated Normal Distribution to Approximate log(t-ratio)

Truncated normal distributions have been used to study publication bias in medical research. The idea is that studies reporting significant results are more likely to get published. Assuming a threshold significance level or t-statistic, researchers can to some extent infer the results of unpublished works and gain understanding of the overall effect of a drug or treatment. However, in medical research, insignificant results are still viewed as an indispensable part of the overall statistical evidence and are given much more prominence than in financial economics research. As a result, medical publications tend to report more insignificant results relative to economics publications. This makes applying the truncated distribution framework to medical studies difficult as there is no clear-cut threshold value. In this sense, the truncated normal distribution framework suits our study better — 1.96 is the obvious hurdle that factors in the literature try to overcome.

On the other hand, not all tried factors with p-value above 1.96 are reported. In particular, factors with "borderline" t-ratios are difficult to get published. Thus, our sample is likely missing a number of works that have t-ratios just over the bar of

<sup>&</sup>lt;sup>44</sup>See Heckman (1979) and Greene (2008), Chapter 24.

<sup>&</sup>lt;sup>45</sup>See Begg and Berlin (1988) and Thornton and Lee (2000).

<sup>&</sup>lt;sup>46</sup>When the threshold value is unknown, it must be estimated from the likelihood function. However, such estimation usually incurs large estimation errors.

1.96. To make our inference robust, for our baseline result, we assume all tried factors with t-ratios above 2.5 are observed and ignore those with t-ratios in the range of (1.96,2.5). We experiment alternative ways to handle t-ratios in this range.

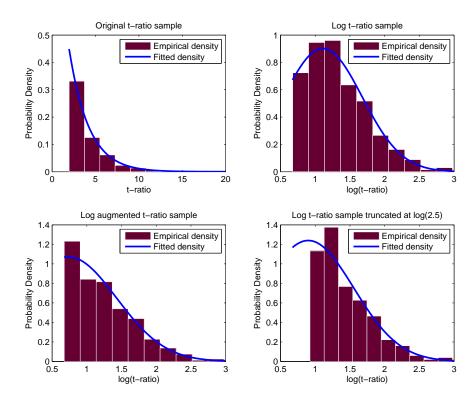

Figure 4: Density Plots for t-ratio and log(t-ratio)

Empirical density and fitted normal density curves based on four different samples. The top two figures are based on the original sample of 186 factors: the left figure includes the original t-ratio sample and the right includes the logarithmic transformed t-ratio sample. The bottom two figures are based on altered log t-ratio samples: the left augments the original sample with observations that fall between  $\log(1.96)$  and  $\log(2.5)$  and the right truncates the original sample at  $\log(2.5)$ .

In Figure 4, the top two plots present histograms of the original t-ratios and log t-ratios. The original t-ratio sample seems to display heavy right tails. Its median, 1st and 3rd quartiles are 3.43, 2.69 and 4.90, respectively, whereas its top one percentile is as high as 12.88. Standard statistical analysis implies the existence of outliers on the right tail.<sup>47</sup> Hence, we need to deal with outliers if directly working with the

 $<sup>^{47}</sup>$ We can use the conventional 1.5 interquartile range (IQR) rule. For a value as high as 12.88, it is more than 1.5 IQR above the 3rd quartile, 4.90. Accordingly, values above 12.88 are outliers.

original sample. As such, we apply a nonlinear transformation to the original data<sup>48</sup> and the shape of the empirical density plot appears more truncated normal.<sup>49</sup> There is another benefit to using logarithmic transformation. It extends the positive support of the t-ratios to the entire real line, making the normality assumption more realistic.

The bottom two plots are histograms of augmented and truncated log t-ratio samples. The left plot is a histogram of the augmented log t-ratio sample assuming our sample covers only half of all factors with t-ratios between 1.96 and 2.5. Rather than guessing the fraction of missing factors, the right plot is a histogram of the truncated sample that discards all t-ratios between 1.96 and 2.5. We also fit normal curves onto the two histograms. We see a large difference between the top right fitted density plot and the bottom two. While the top right plot has a normal distribution centered well within one, the bottom two are centered below one. Consequently, the top right plot implies that less than 50% of tried factors are unobserved while the bottom two imply a number that is higher than 50%.

We focus on the sample that is further truncated at  $\log(2.5)$ . Assuming independence, we model observed log t-ratios as following a truncated normal distribution with unknown mean and variance but a known cutoff point  $\log(2.5)$ . The Maximum Likelihood Estimates (MLE) of the truncated normal distribution are  $\hat{\mu} = 0.90$  and  $\hat{\sigma} = 0.66$ . Based on these estimates, we can calculate the mean t-ratio and the proportion of unobserved factors (including factors with t-ratio less than 2.5) as:

$$E(\text{t-ratio}) = \exp(\hat{\mu} + \frac{1}{2}\hat{\sigma}^2) = 3.06,$$
 (A.1)

$$P(\text{unobserved}) = \Phi(\log(2.5); \hat{\mu}, \hat{\sigma}) = 51.0\%,$$
 (A.2)

where  $\Phi(c; \mu, \sigma)$  is the cumulative distribution function evaluated at c for a normal distribution with mean  $\mu$  and variance  $\sigma^2$ . Our estimates indicate that the mean t-ratio for the underlying factor population is 3.06 and about 51% of tried factors are discarded. Given that 241 out of the original 314 factors have a t-ratio exceeding 2.5, the total number of factor tests is estimated to be 492 (= 241/(1 – 51%)) and the number of factors with a t-ratio between 1.96 and 2.5 is estimated to be 71. Since our t-ratio sample covers only 53 such factors, roughly 34% (=(71-53)/53) of t-ratios between 1.96 and 2.5 are missing.

 $<sup>^{48}</sup>$ For the transformed data, the median, 1st and 3rd quartiles are 1.23, 0.99 and 1.59, respectively. The top one percentile is 2.55. Although 2.55 is still above 1.5IQR + 1.59 = 2.49, their difference, relative to the sample median, is much smaller than the non-transformed sample.

<sup>&</sup>lt;sup>49</sup>Strictly speaking, we should search among a parametric family of nonlinear transformations to find the one that best fits the data. However, such statistical techniques are not well established for truncated distributions. Following other applied works that use truncated normal distributions, we adopt a simple transformation that seems to describe the data well.

<sup>&</sup>lt;sup>50</sup>Directly applying our estimation framework to the original sample that includes all t-ratios above 1.96, the estimated total number of factor tests would be 377. Alternatively, assuming our sample only covers half of the factors with t-ratios between 1.96 and 2.5, the estimated number of factor tests is 649.

### A.2 Simulated Benchmark t-ratios Under Independence

The truncated normal distribution framework helps us learn the distribution of tratios for all factors, published and unpublished. We can then apply the aforementioned adjustment techniques to this distribution to generate new t-ratio benchmarks. However, there are two sources of sampling and estimation uncertainty that affect our results. First, our t-ratio sample may under-represent all published factors with t-statistics exceeding 2.5. Hence, our estimates of total trials are biased (too low), which affects our calculation of benchmarks. Second, estimation error for the truncated normal distribution can affect our benchmark t-ratios. Although standard asymptotic distribution theory for MLE applies to truncated distributions, it is unclear how we should compute t-ratio benchmarks based on the asymptotic distribution. This is because t-ratio adjustment procedures usually depend on the entire t-ratio distribution and so standard transformational techniques (e.g., delta method) do not apply. Moreover, we are not sure whether our sample is large enough to trust the accuracy of asymptotic approximations.

Given these concerns, we propose a simulation framework that incorporates these uncertainties. We divide it into four steps:

#### Step I Estimate $\mu, \sigma$ and M based on a new t-ratio sample with size $r \times R$ .

Suppose our current t-ratio sample size is R. We sample  $r \times R$  t-ratios (with replacement) from the original t-ratio sample. Based on this new t-ratio sample, we apply the above truncated normal distribution framework to the log t-ratios and obtain the parameter estimates  $\hat{\mu}$  and  $\hat{\sigma}$  for the normal distribution. The truncation probability is calculated as  $\hat{P} = \Phi(\log(2.5); \hat{\mu}, \hat{\sigma})$ . We can then estimate the total number of trials by

$$\hat{M} = \frac{rR}{1 - \hat{P}}$$

# Step II Calculate the benchmark t-ratio based on a random sample generated from $\hat{\mu}, \hat{\sigma}$ and $\hat{M}$ .

Based on the previous step estimate of  $\hat{\mu}$ ,  $\hat{\sigma}$  and  $\hat{M}$ , we generate a random sample of t-ratios for all tried factors. We then calculate the appropriate benchmark t-ratio based on this generated sample.

#### Step III Repeat Step II many times to get the median benchmark t-ratio.

Repeat Step II (based on the same  $\hat{\mu}, \hat{\sigma}$  and  $\hat{M}$ ) many times to generate a collection of benchmark t-ratios. We take the median as the final benchmark t-ratio corresponding to the parameter estimate  $(\hat{\mu}, \hat{\sigma}, \hat{M})$ .

# Step IV Repeat Step I-III many times to generate a distribution of benchmark t-ratios.

Repeat Step I-III N times, each time with a newly generated t-ratio sample as in Step I. For each repetition, we obtain a benchmark t-ratio  $t_i$  corresponding to the parameter estimates  $(\hat{\mu}_i, \hat{\sigma}_i, \hat{M}_i)$ . In the end, we have a collection of benchmark t-ratios  $\{t_i\}_{i=1}^N$ .

To see how our procedure works, notice that Steps II-III calculate the theoretical benchmark t-ratio for a t-ratio distribution characterized by  $(\hat{\mu}, \hat{\sigma}, \hat{M})$ . As a result, the outcome is simply one number and there is no uncertainty around it. Uncertainties are incorporated in Steps I and IV. In particular, by sampling repeatedly from the original t-ratio sample and re-estimating  $\mu$ ,  $\sigma$  and M each time, we take into account estimation error of the truncated normal distribution. Also, under the assumption that neglected significant t-ratios follow the empirical distribution of our t-ratio sample, by varying r, we can assess how under-representation of our t-ratio sample affects results.

Table 7 shows estimates of M and benchmark t-ratios for both the original sample (Panel A) and trimmed sample (Panel B). In Panel A, when r=1, the median estimate for the total number of trials is 482,  $^{51}$  almost the same as our previous estimate of 492 based on the original sample. Unsurprisingly, Bonferroni implied benchmark t-ratio (3.88) is larger than 3.78, which is what we get ignoring unpublished works. Holm implied t-ratio (3.79), while not necessarily increasing in the number of trials, is also higher than before (3.64). BHY implied t-ratio increases from 3.38 to 3.51 at 1% significance and from 2.78 to 2.97 at 5% significance. As r increases, sample size M and benchmark t-ratios for all four types of adjustments increase. When r doubles, the estimate of M also approximately doubles and Bonferroni and Holm implied t-ratios increase by about 0.2, whereas BHY implied t-ratios increase by around 0.04 (under both significance levels).

Comparing Panel A and Panel B, the change in the estimate of M is large: although dropping only two observations, the estimate of M decreases by more than 100. The change in benchmark t-ratios, on the other hand, is small and ranges from 0.05 to 0.10. Unlike conventional sample statistics (e.g., mean and variance), adjusted t-ratios rely on sample order statistics and are thus relatively robust to outliers. In sum, across all specifications, we think a robust t-value threshold is 3.7 for both Bonferroni and Holm at 5%, 3.4 for BHY at 1% and 2.9 for BHY at 5%.

<sup>&</sup>lt;sup>51</sup>Our previous estimate of 492 is a one-shot estimate based on the truncated sample. The results in Table 7 are based on repeated estimates based on re-sampled data: we re-sample many times and 482 is the *median* of all these estimates. It is close to but not exactly the one-shot estimate.

Table 6: Benchmark t-ratios When M is Estimated

Estimated total number of factors tried (M) and benchmark t-ratio percentiles based on a truncated normal distribution framework. Our estimation is based on the original log t-ratio sample truncated at  $\log(2.5)$ . The sampling ratio is the assumed ratio of the true population size of t-ratios exceeding 2.5 over our current sample size. Panel A reports estimates for the full sample while Panel B reports those based on the sub-sample with the top 1% trimmed. Both Bonferroni and Holm have a significance level of 5%.

### B A Simple Bayesian Framework

The following framework is adopted from Scott and Berger (2006). It highlights the key issues in Bayesian multiple hypothesis testing.<sup>52</sup> More sophisticated generalizations modify the basic model but are unlikely to change the fundamental hierarchical testing structure.<sup>53</sup> We use this framework to explain the pros and cons of performing multiple testing in a Bayesian framework.

The hierarchical model is as follows:

**H1.** 
$$(X_i|\mu_i, \sigma^2, \gamma_i) \stackrel{iid}{\sim} N(\gamma_i\mu_i, \sigma^2),$$

**H2.** 
$$\mu_i | \tau^2 \stackrel{iid}{\sim} N(0, \tau^2), \gamma_i | p_0 \stackrel{iid}{\sim} Ber(1 - p_0),$$

**H3.** 
$$(\tau^2, \sigma^2) \sim \pi_1(\tau^2, \sigma^2), p_0 \sim \pi_2(p_0).$$

We explain each step in detail as well as the notations:

**H1.**  $X_i$  denotes the average return generated from a long-short trading strategy based on a certain factor;  $\mu_i$  is the unknown mean return;  $\sigma^2$  is the common variance for returns and  $\gamma_i$  is an indicator function, with  $\gamma_i = 0$  indicating a zero factor mean.  $\gamma_i$  is the counterpart of the reject/accept decision in the usual (frequentists') hypothesis testing framework.

H1 therefore says that factor returns are independent conditional on mean  $\gamma_i \mu_i$  and common variance  $\sigma^2$ , with  $\gamma_i = 0$  indicating that the factor is spurious. The common variance assumption may look restrictive but we can always scale factor returns by changing the dollar investment in the long-short strategy. The crucial assumption is conditional independence of average strategy returns. Certain form of conditional independence is unavoidable for Bayesian hierarchical modeling<sup>54</sup> — probably unrealistic for our application. We can easily think of scenarios where average returns of different strategies are correlated, even when population means are known. For example, it is well known that two of the most popular factors, the Fama and French (1992) HML and SMB are correlated.

<sup>&</sup>lt;sup>52</sup>We choose to present the full Bayes approach. An alternative approach — the empirical-Bayes approach — is closely related to the BHY method that controls the *false-discovery rate* (FDR). See Storey (2003) and Efron and Tibshirani (2002) for the empirical-Bayes interpretation of FDR. For details on the empirical-Bayes method, see Efron, Tibshirani, Storey and Tusher (2001), Efron (2004) and Efron (2006). For an in-depth investigation on the difference between the full Bayes and the empirical-Bayes approach, see Scott and Berger (2010).

<sup>&</sup>lt;sup>53</sup>See Meng and Dempster (1987) and Whittemore (2007) for more works on the Bayesian approach in hypothesis testing.

<sup>&</sup>lt;sup>54</sup>Conditional independence is crucial for Bayesian network and the construction of posterior likelihoods. Although it can be extended to incorporate special dependence structures, there is no consensus on how to systematically handle dependence. See Brown et al. (2012) for a discussion of independence in Bayesian multiple testing. They also incorporate a spatial dependence structure into a Bayesian testing framework.

**H2.** The first step population parameters  $\mu_i$ 's and  $\gamma_i$ 's are assumed to be generated from two other parametric distributions:  $\mu_i$ 's are independently generated from a normal distribution and  $\gamma_i$ 's are simply generated from a Bernoulli distribution, i.e.,  $\gamma_i = 0$  with probability  $p_0$ .

The  $\mu_i$ 's are normally distributed. This requires the reported  $X_i$ 's to randomly represent either long/short or short/long strategy returns. If researchers have a tendency to report positive abnormal returns, we need to randomly assign to these returns plus/minus signs. The normality assumptions in both H1 and H2 are important as they are necessary to guarantee the properness of the posterior distributions.

**H3.** Finally, the two variance variables  $\tau^2$  and  $\sigma^2$  follow a joint prior distribution  $\pi_1$  and the probability  $p_0$  follows a prior distribution  $\pi_2$ .

Objective or "neutral" priors for  $\pi_1$  and  $\pi_2$  can be specified as:

$$\pi_1(\tau^2, \sigma^2) \propto (\tau^2 + \sigma^2)^{-2}$$
  
 $\pi_2(p_0) = \text{Uniform}(0, 1)$ 

Under this framework, the joint conditional likelihood function for  $X_i$ 's is simply a product of individual normal likelihood functions and the posterior probability that  $\gamma_i = 1$  (discovery) can be calculated by applying Bayes' law. When the number of trials is large, we need efficient methods such as importance sampling, which involves high dimensional integrals, to calculate the posterior probability.

One benefit of a Bayesian framework for multiple testing is that the multiplicity penalty term is already embedded. In the frequentists' framework, this is done by introducing FWER or FDR. In a Bayesian framework, the so-called "Ockham's razor effect" <sup>55</sup> automatically adjusts the posterior probabilities when more factors are simultaneously tested. <sup>56</sup> Simulation studies in Scott and Berger (2006) show how the discovery probabilities for a few initial signals increase when more noise are added to the original sample.

However, there are several shortcomings for the Bayesian approach. First, the hierarchical testing framework may be overly restrictive. Both independence as well as normality assumptions can have a large impact on the posterior distributions. Although normality can be somewhat relaxed by using alternative distributions, the scope of alternative distributions is rather limited as there are only a few distributions that can guarantee the properness of the posterior distributions. Independence, as we previously discussed, is likely to be violated in our context. In contrast, the three adjustment procedures under the frequentists' framework are able to handle complex

<sup>&</sup>lt;sup>55</sup>See Jefferys and Berger (1992).

<sup>&</sup>lt;sup>56</sup>Intuitively, more complex models are penalized because extra parameters involve additional sources of uncertainty. Simplicity is rewarded in a Bayesian framework as simple models produce sharp predictions. See the discussions in Scott (2009).

data structures since they rely on only fundamental probability inequalities to restrict their objective function — the Type I error rate.

Second, it is not clear what to do after obtaining the posterior probabilities for individual hypotheses. Presumably, we should find a cutoff probability P and reject all hypotheses that have a posterior discovery probability larger than P. But then we come back to the initial problem of finding an appropriate cutoff p-value, which is not at all a clear task. Scott and Berger (2006) suggest a decision-theoretic approach that chooses the cutoff P by minimizing a loss-function. The parameters of the loss-function, however, are again subjective.

Lastly, the Bayesian posterior distributions are computationally challenging. When M gets large (say, in the hundreds), importance sampling is a necessity. However, results of importance sampling rely on simulations and subjective choices of the centers of the probability distributions for random variables. Consequently, two researchers trying to calculate the same quantity might get very different results. Moreover, in multiple testing, the curse of dimensionality generates additional risks for Bayesian statistical inference.<sup>57</sup> These technical issues create additional hurdles in the application of the Bayesian approach.

### C FAQ

### C.1 Specific Questions

• Why is FWER called "rate" when it is a single number? (Section 4.3)

FWER has been used by the statistics literature a long time ago, even before 1979. However, Holm (1979) seems to be the first one that formally defines the family-wise error rate. Terms used in Holm (1979) are different from our current presentation. Our "family-wise" terminology is likely first mentioned in Cox (1982) and later formally defined in Hochberg and Tamhane (1987). "Rate" is the standard terminology nowadays, though we are not sure of the historical reason for calling it "rate" instead of probability. But we notice people using "Type I error rate" instead of "Type I error probability" in single hypothesis testing. We think that "probability" can be used interchangeably with "rate" since "probability" is "rate" in frequentists' view.

• How can we tell in real time the errors? (Section 4.3.2)

We never know the "true" errors. Even with out-of-sample testing, all we can tell is how likely it is for a factor to be "real" for one particular *realization* of historical returns.

• Is it possible to set the actual Type I error rate to be exactly at the pre-specified level? (Section 4.3.2)

Any adjustment procedure has a theoretically implied upper bound on the Type I error rate. This bound is the "actual Type I error rate" (as opposed to the realized Type I error rate for a particular outcome of a multiple test) and usually achievable under specific distributional assumptions (e.g.,negative dependence among p-values as in BHY). We usually use the distance between this bound and the pre-specified significance level to measure the goodness of a procedure. In reality, for a particular sequence of p-value realizations, e.g., 186 p-values for our 186 factors, we cannot do much. By following a specific adjustment procedure, we can say what the maximal expected Type I error rate is if we repeat such multiple testing many times, each time with a different p-value sequence. Comparing two procedures A and B, we want to know whether the expected Type I error rate (after integrating out the randomness in the return data) under A is closer to the significance level than it is under B. It makes little sense to compare A and B based on a particular outcome (e.g., 186 p-values) of a multiple test.

• Why doesn't the t-value go to something much larger than 3.5 after so many tests (Section 4.6)

We report t-ratios not p-values. Suppose you start with a cutoff p-value of 0.05. For a single test, the t-ratio needs to be 2.0 or above. Now consider a multiple testing framework. For simplicity, consider the Bonferroni test. If there are two tests, appropriate cutoff is a p-value of 0.025. For 10 tests, the p-value drops to 0.005. The table below shows the number of multiple tests necessary for certain levels of t-ratios. For example, if we had 87,214 tests, then the Bonferroni would require the factor to have a t-ratio of 5.0 to be deemed significant (p-value of 0.00000057).

Table 7: Bonferroni t-ratios and Required Number of Tests

Bonferroni t-ratios, cut-off p-values and the required number of tests.

t-ratio	p-value	# of Bonferroni tests
2	0.05	1
3	0.0027	19
4	0.000063	789
5	0.00000057	87,214
6	0.0000000020	25,340,000
7	$2.56 \times 10^{-12}$	$1.95 \times 10^{10}$
8	$1.33 \times 10^{-15}$	$3.75 \times 10^{13}$

• Why is there a drop for the time-series of BHY implied t-ratios? (Section 4.6)

In Figure 3, there seems to be a drop for BHY implied t-ratios around 1995. Unlike Bonferroni or Holm, BHY implied benchmark t-ratios are not necessarily monotonically increasing in the number of factors. This is because false discovery rate (FDR) is about the proportion of false discoveries among all discoveries. Given a set of t-ratios for the years before 1995, suppose we find the BHY implied adjusted t-ratio. In year 1995, suppose we observe a set of large t-ratios. These large t-ratios will likely increase the denominator of FDR (i.e., the number of discoveries R). At the same time, they are unlikely to increase the numerator (i.e., the number of false discoveries  $N_{0|r}$ ). As a result, including this new set of large t-ratios into the previous t-ratio set, the new BHY implied benchmark t-ratio will likely decrease. The highly significant t-ratios for 1995 dilute the proportion of false discoveries made based on the t-ratios from previous years.

• Is "...control their Type I error rates under arbitrary distributional assumptions" really true? Suppose we had 186 factors but they were 99% correlated — effectively just one factor. This seems to me to be a situation where independent test criterion is appropriate. (Section 4.7)

The statement is correct and the concern is about the Type II rather than Type I error of the testing procedure. In the example, it is true that independent criterion makes more sense. But multiple testing procedures are also able to control the Type I error rates, albeit too much in this case. For instance, Bonferroni implies a threshold t-ratio of 3.5 when there are 186 factors. If most of the factors are perfectly correlated, then the FWER under Bonferroni's criterion is effectively zero. Since zero is less than any pre-specified significance level, the tests still control what they are supposed to control — Type I error rate (FWER or FDR). Of course, the power of the test, which, as previously discussed, can be measured by the distance between the actual Type I error rate and the pre-specified level, would be too low.

• How does incomplete coverage of "significant" factors affect our results? (Section 4.7)

It is likely that our sample somewhat under-represents the population of significant factors. As previously discussed, there are a number of causes for this under-coverage. First, there are some truly significant factors that were tested as insignificant and never made it to publication. Second, we are highly selective in choosing among working papers. Third, we only consider the top three finance journals in choosing among published works. This under-coverage will impact our t-value cutoffs. To quantitatively evaluate this impact, we tabulate a new set of cutoffs: those generated under different degrees of under-representation of the population of significant factors. Table 8 reports the cutoff t-statistics for 2012. Assuming a true population size over our sample size ratio of r, we report adjusted t-ratios for our three approaches.<sup>58</sup> The top row corresponds to a sample size ratio of one, i.e., our original sample. We see that when the true population is twice as large as our sample, Bonferroni implied benchmark t-ratio increases from 3.78 to 3.95 and Holm from 3.64 to 3.83. Relative to the percentage change in t-ratios, the corresponding change in p-values is large. For Bonferroni, p-value changes from 0.016% to 0.008%; for Holm from 0.027% to 0.013%. Both p-values drop by at least half. For BHY, however, the change is less dramatic. This is consistent with our previous discussion of the stationarity of BHY. In sum, we think a robust t-ratio range for Bonferroni and Holm is 3.6-4.0; for BHY, 3.35-3.45 when  $\alpha_d = 1\%$  and 2.80-2.85 when  $\alpha_d = 5\%$ .

 $<sup>^{58}</sup>$ Assuming this r ratio and sample size N, we obtain Bonferroni adjusted t-ratios straightforwardly based on total number of factors Nr. For Holm and BHY, we sample (with replacement) N(r-1) values from the recent 10 years' t-ratios sample. Together with the original sample, we have an augmented sample of Nr t-ratios. We follow Holm or BHY to get the adjusted t-ratio benchmarks for each augmented sample. Finally, we generate W=1000 such augmented samples and take the median as the final benchmark t-ratio. When Nr or N(r-1) are not integers, we use the smallest integer that is greater than or equal to Nr and N(r-1), respectively.

Table 8: Cutoff t-ratios for Alternative Sample Sizes

Benchmark t-ratios and their associated p-values for the three multiple testing adjustments for 2012. Sample size ratio is true population size over our sample size. Both Bonferroni and Holm have a significance level of 5%.

Sample size ratio $(r)$	Bonferroni	Holm	BHY(1%)	BHY(5%)
for significant factors	[p-value]	[p-value]	[p-value]	[p-value]
1	3.78	3.64	3.38	2.78
	[0.016%]	[0.027%]	[0.072%]	[0.544%]
2	3.95 [0.008%]	3.83 [0.013%]	3.39 [0.070%]	2.81 [0.495%]
3	4.04 [0.005%]	3.93 [0.008%]	3.43 [0.060%]	2.84 [0.451%]

• Haven't there been recent advances in Bayesian literature with respect to multiple testing? (Appendix B)

In papers that apply the Bayesian testing method, there are many new ways that try to handle inadequacies. For instance, to relax the independence assumption, Brown et al. (2012) introduce an autoregressive dependence structure because their data are obtained sequentially. But they have to assume that noise from the autoregressive processes is independent from the rest of the system. Conditional independence is key to Bayesian modeling. There are ways to circumvent it, but most methods are data-driven and not applicable in our context. For instance, it is unclear how to model dependence among the test statistics of factors in our list. The indeterminacy of the cutoff is mentioned in Scott and Berger (2006). There are many applied works that propose ad hoc methods to try to establish a threshold. Finally, computational difficulty is a longstanding issue in Bayesian literature. People often discard Bayesian methods because they incorporate a "subjective" prior (i.e., generate random samples around a region where researchers "believe" the parameters should be concentrated) into their posterior calculation. Multiple testing introduces dimensionality concerns, and it is well-known that posterior distributions are hard to calculate accurately when the dimensionality is high. In sum, we think the above three issues are generic to the Bayesian multiple testing framework and for which there are no simple/systematic solutions.

### C.2 General Questions

• What if the underlying data are non-stationary in that as anomalies are discovered, they are arbitraged away; some newer frictions/biases arise, they are discovered, and then arbitraged away, and so on? This seems like a possible alternative that would lead to the creation of more and more factors over time, without necessarily implying that the t-ratio ought to be raised for newer factors.

Our preferred view is that the factor universe is a combination of some stationary factors that cannot be arbitraged away (systematic risk) and some other transitory factors that can be arbitraged away once discovered. As time goes by and we accumulate more data, stationary factors tend to become more significant (t-ratio proportional to the square root of the number of time periods). Through our multiple testing framework, the adjusted benchmark t-ratio becomes higher. This higher bar helps screen newly discovered transitory factors. In other words, it should be harder to propose new transitory factors as longer sample is available. Without multiple testing, recent transitory factors are just as likely to be discovered as past transitory factors. This means that the discovery rate for transitory factors will remain high (if not higher) as time goes by. This is exactly the trend that we try to curb. Ideally, the finance profession should focus on systematic/stationary factors rather than transitory abnormalities.

• What if many of the factors are highly correlated or at least within a "span" other than the common 3-4 factors like the Fama-French three factors and Momentum which are controlled for while finding new factors? That is, is it possible that the literature has just been rediscovering "new" factors but they remain spanned by other documented factors that did not become an "industry" like Fama-French three factors and Momentum factors?

This is possible, although as we mentioned in the paper, newly proposed factors often need to "stand their ground" against similar factors (not just Fama-French three factors and Momentum) that are previously proposed. All of our three adjustments are robust to correlations among the factors. This means that the Type I error (rate of false discoveries) is still under control. However, high correlations make our adjustment less powerful, that is, the benchmark t-ratio is too high for a new factor to overcome. However, given the hundreds of factors proposed, we think it is time to worry more about the Type I error than the power of the tests. A recent paper by Green, Han and Zhang (2013) show that the correlations among strategy signals are low on average. This seems to suggest that new factors proposed in the literature are somewhat independent from past ones.

• Should the benchmark t-ratios be higher simply because the number of data points has increased through time?

For a single, independent test, the t-ratio threshold should remain constant through time. For a return series that has a mean and variance, it is true that its t-ratio will increase as we have more data points. However, this does not imply a higher t-value threshold for hypothesis testing. At 5% significance level, we should always use 2.0 for single test as it gives the correct Type I error rate under the null hypothesis that mean return is zero. As time goes by, truly significant factors are more likely to be identified as significant and false factors are more likely to be identified as insignificant. In other words, the power of the test is improved as we have more observations but this should not change the cutoff value.

In fact, when the sample size is extremely large, it becomes very easy to generate large t-statistics. In this case, people often use alternative statistics (e.g., odds ratios) to summarize strategy performance.
